1 Introduction

Cooperation among different individuals in a group is often necessary to solve complex problems that are otherwise harder or impossible to complete for a singular individual. This concept is true in the field of robotics, where robotic swarms systems, which are systems composed of numerous small and limited robots (Oh et al. 2017), are a crucial area of study. Due to the early stage of development of this field, there are not many currently existing applications, however there exists many research projects to test the capabilities of swarm algorithms (Schranz et al. 2020). Despite the lack of representation in the industry sector, multi-robot systems have become of interest recently due to their abilities to resist failures and damages, adaptability to new environments and low costs (Oh et al. 2017).

A specific problem in swarm robotics, is the pattern formation problem, which consists of "getting a group of robots to form and stay in a specific formation, like a wedge or a chain, and maintaining that formation" (Sri and Suvarchala 2022). The robots in the swarm need to coordinate to maintain a specific shape in order to achieve the desired goal. In this process, different methods of controlling the swarm can be used, for example the election of a leader or the imposition of a certain set of behaviors for each member. There is also a distinction between centralized and decentralized pattern formation, where centralized pattern formation is performed when there exists a centralized unit that coordinates the individual robots (Oh et al. 2017).

In this project we will explore a decentralized and distributed solution to the pattern formation problem. A distributed approach was chosen because of their robustness to failure, due to their built-in redundancy since each robot in the swarm receives the same role (Oh et al. 2017). This is advantageous compared to a centralized, non-distributed approach as it mitigates the possibility of a single point of failure.

1.1 Swarms of Unmanned Aerial Vehicles

A swarm of Unmanned Aerial Vehicles is a swarm of robots where each robot is capable of flight using a set of rotors. These swarms have multiple uses. They are commonly used in military applications, but they are also used for civilian applications, such as aerial surveys, disaster management, environment mapping, search and rescue and for leisure (Tahir et al. 2019). These are applications that would benefit from pattern formation, as we can direct the swarm to take an optimal shape for its use case. For example, we can choose a shape to best cover an area while performing an aerial survey

or environment mapping, or adopt a chain-like formation to establish communication between two points (Schranz et al. 2020) which can be deployed at a site of a natural disaster to aid in search and rescue efforts.

1.2 Objectives

The objective of this project is to provide a distributed solution to the pattern formation problem, meaning build a system of multiple robots capable of positioning themselves in a specific shape and maintain this shape while navigating an environment dotted by obstacles. This will be achieved using obstacle detection and avoidance techniques, as well as distributed system principles, such as leader election, and computer network principles. For this project we chose to use unmanned aerial vehicles to demonstrate the efficacy of the solution. Similar work being done includes (Chen et al. 2021), where a hierarchical approach is applied to formation control of fixed wing UAVs, by breaking up the swarm into several smaller groups headed by a leader.

2 Methodology

In this chapter we will explore the method used in and considered for this project. Since this project contains multiple sub-problems we decided to divide this chapter into four sections.

2.1 Automated flight

The first consideration for this project is about the autonomous flight of the UAVs, meaning that there should not be any input from the user regarding the flight control. This problem can then be broken down into two components: the control algorithm that controls the ability of the UAV to fly and the navigation algorithm that controls the direction of flight.

2.1.1 Control Algorithm

Flight controllers can be subdivided into two categories: linear controllers and non-linear controllers. Linear controllers use linear methods to control flight, which includes conventional controllers such as PID, H_∞ controller, gain scheduling and Linear Quadratic Regulator. While non-linear controller are derived from the original dynamic model of the UAVs and arose to overcome shortcomings of linear controllers. They are generally harder to implement. Some examples are Feedback linearization, backstepping, sliding mode control, adaptive control, and model predictive control. (Nguyen et al. 2020)

For this project we settled on linear controller due to their simplicity to implement, in particular we considered the PID controller and the LQR controller.

PID Control

The Proportional Integral Derivative controller is the most common controller used in industrial settings due to its usefulness and ease of implementation. (Lopez-Sanchez and Moreno-Valenzuela 2023) The controller is composed by a proportional element, an integral element and a derivative element, that represent the present, past and future error value(Araki 2009).

Figure 2.1: Diagram of a conventional PID controller

The controller first computes the error at a specific time t ($e(t)$) using Eq. 2.1.

$$e(t) = r(t) - y(t) \quad (2.1)$$

Where $r(t)$ is the set value and $y(t)$ is the real value of the process (Araki 2009). From the computed error the controller then finds a control factor $u(t)$ using a proportional coefficient (K_p), an integral coefficient (K_I) and a derivative coefficient (K_D) using Eq. 2.2 (Nguyen et al. 2020).

$$u(t) = K_p e(t) + K_I \int_0^t e(t) dt + K_D \frac{de(t)}{dt} \quad (2.2)$$

LQR Control

The other option considered, is the Linear-Quadratic Regulator controller (LQR controller), which is the optimal linear controller to operate a dynamic system at minimum cost (Nguyen et al. 2020).

$$J_{LQR} = \int_0^\infty y_i^T(t) Q y_i(t) + u_i^T(t) R u_i(t) dt \quad (2.3)$$

Eq. 2.3 computes the minimum quadratic cost (J_{LQR}) from the control input u_i and control output y_i , using two weight matrices (Q and R) (Nguyen et al. 2020).

2.2 Obstacle Detection

2.3 Obstacle Avoidance

2.4 Pattern Formation
